The functional polymeric nanofilm of 6-diallylamino-1,3,5-triazine-2,4-dithiol monosodium (DAN) was successfully prepared by cyclic voltammetry and galvanostatic technique in NaNO₂ supporting electrolyte on pure aluminum surface. Based on results of cyclic voltammetry and X-ray photoelectron spectroscopy (XPS), the mechanism of electrochemical polymerization was speculated, which indicated that the radical polymerization took place during the electrochemical polymerization process. The poly(6-diallylamino-1,3,5-triazine-2,4-dithiol) (PDA) functional nanofilm was also investigated by means of FT-IR spectra. The result also showed that the structure of polymeric nanofilm was consisted of Al₂O₃ and PDA. And the optimal electrochemical polymerization time of DAN at current density of 0.2 mA/cm² at 298 K in NaNO₂ solution is 6 min. It is expected that electrochemical polymerization technique will bring the direct joining between aluminum and rubber in the process of curing with the formed polymeric nanofilm.

Keywords: Triazinedithiol monosodium, aluminum, functional polymeric nanofilm, electrochemical polymerization

1. INTRODUCTION

The pre-treatment of aluminum surface prior to painting or adhesive bonding is an essential technology in industrial fields. However, most of the pre-treatments are based on chromates, which are hazardous to environment and human health. Thus, much effort has been made to develop environment-friendly systems [1, 2].

Since the publication of Mori K’s results on the corrosion protection properties of triazinedithiols (TDTs) on copper surface [3], the adsorption and polymerization of TDTs on metal
surfaces have been receiving increasing attention, which could be used in corrosion-resistant in place of chromate-based treatment. Experimental researches showed that polymeric films prepared by different TDTs had a basic performance-anticorrosion property [4], with inhibition efficiency ranging from 6.1 to 92.8% according to different structures of substituent groups. Thus, during the last decades, there were many studies about other applications of TDTs polymeric film, such as adhesion [5], lubrication property [6], dielectric property [7] and superhydrophobicity [8] on various metal substrates [9-17].

Monomer layer of triazinedithiols (TDTs) on metal surfaces can be polymerized mechanochemically [6], photochemically [18], thermochemically [9], electrochemically [10] or evaporatingly [19]. The electrochemical polymerization process offers advantages of the simultaneity of adsorption and polymerization on metal surface in monomer-electrolyte solution, and the possibility of controlling their chemical and physical properties by changing electrochemical parameters (e.g. current density, potential, monomer concentration, supporting electrolyte, etc). The electrochemical polymerization of TDTs, also referred to as polymer plating [12], on magnesium alloys [20], iron [10], cast iron [21] and copper surfaces [22] had been studied systematically. Poly(6-diallylamino-1,3,5-triazine-2,4-disulfide) (PDA) films on spheroidal-graphite cast iron [21] and magnesium/magnesium alloy [20] had been prepared successfully by means of electrochemical polymerization. The former showed direct joining of acrylic rubber to the cast iron in the process of curing, and the latter exhibited excellent adhesion to ethylene-propylene-diene monomer (EPDM) in a peroxide curing system. High peel strength adherend of rubber/metal was obtained by the suitable film thickness and good quality of film under curing condition. In other words, the film thickness had considerable effect on peel strength and rubber coverage of adherends.

So far, adhesion research between rubber and aluminum treated with TDTs has not been studied and reported. Therefore, it is necessary to study the electrochemical polymerization parameters for preparing PDA film on aluminum surface to find the optimal conditions for future application of PDA film used for adhesion with rubber. 6-diallylamino-1,3,5-triazine-2,4-dithiol monosodium (DAN) has the reactivity to metals/metallic oxides with dithiol functional groups and the affinity to rubbers with allyl groups. In this work, the study on electrochemical polymerization of 6-diallylamino-1,3,5-triazine-2,4-dithiol monosodium (DAN) on aluminum plate was investigated by cyclic voltammetry and galvanostat methods. The polymerization mechanism was also proposed.

2. EXPERIMENTAL DETAILS

2.1. Materials

Test specimens (50 × 30 × 0.1 mm) of pure aluminum (purity no less than 99.9995%) were prepared by cutting a large plate into pieces. All test plates were degreased by ultrasonic washing in acetone for 15min, and dried in nitrogen air. 6-diallylamino-1,3,5-triazine-2, 4-dithiol monosodium was synthesized by the reaction of 1,3,5-triazine-2,4,6-trichloride with diallyl amine and NaSH, according to the method described in the previous paper [12]. All of the chemicals were employed as
analytical reagent (AR) without any further treatment. Distilled water was used as solvent, while NaNO$_2$ (pH=7.17), Na$_2$CO$_3$ (pH=10.25) and Na$_2$SO$_3$ (pH=6.32) were applied as supporting electrolytes. The concentrations of DAN and supporting electrolytes were kept constant at 5 mM and 0.15 M, respectively.

2.2. Preparation of polymeric nanofilm

The electrochemical polymerization of DAN was performed by using electrochemical measurement apparatus (CHI660C). The electrolytic cell was equipped with working electrode (aluminum plates), Pt counter electrode and reference electrode (saturated calomel electrode, SCE), then was filled with electrolytic solution containing DAN in distilled water. Cyclic voltammetry was carried out at a sweep rate $|\frac{dE}{dt}|=10$ mVs$^{-1}$. Galvanostatic electrochemical polymerization of current density was 0.2 mAcm$^{-2}$ according to previous study [7]. The whole process was conducted at 298 K without any stirring.

2.3. Characterization

Electronic balance with measurement accuracy of 0.01 mg (CP225D, Sartorius) was used to examine the polymeric nanofilm weight before and after electrochemical polymerization. Polymeric nanofilm thickness was measured by using JASCO M-150i ellipsometer (Jasco Tokyo Japan). FT-IR spectra were carried out at a resolution of 4 cm$^{-1}$ using JASCO IR-5500 (Jasco Tokyo Japan) by high-performance reflection absorption spectroscopy (RAS). A reflection attachment was used at an incident angle of 80° together with a wire grid polarizer. X-ray photoelectron spectroscopy (XPS) was performed to determine the elemental composition of aluminum surface. Spectra were obtained by using ULVAC PHI-5600 spectrometer equipped with monochrome Al Kα radiation (1,486.6 eV). The pressure in preparation chamber was less than $10^{-7}$ Torr and less than $4 \times 10^{-10}$ Torr in analysis chamber. Samples were examined over an area of $800 \times 2,000 \mu$m, and photoelectron spectra were recorded with a take-off angle of 45°. The blank and PDA-covered surfaces were also observed by SEM (JSM-6360LV) at accelerating voltage of 20 kV.

3. RESULTS AND DISCUSSION

3.1. Effect of supporting electrolyte on electrochemical polymerization

In order to find the optimal electrolyte for electrochemical polymerization on aluminum surface, the FT-IR spectra obtained after galvanostat polymerization were analyzed (Fig. 1). The results were totally different for three kinds of electrolytes. As for NaNO$_2$, the absorption bands centered at 1481, 1536 and 1566 cm$^{-1}$ were assigned to C=N and C-N groups of triazine ring [10]. The bands at 2927, 2860 and 2968 cm$^{-1}$ were assigned to CH$_2$ and CH groups of allyl chain. The bands at 1645 and 3090, 2975 cm$^{-1}$ were assigned to C=C and =CH$_2$ groups. It is well known that aluminum is easily oxidized to form Al$^{3+}$ species and the Al$^{3+}$ encounters water to form a thin, stable, insulated and
protective Al<sub>2</sub>O<sub>3</sub> oxide film on the surface. The band at 960 cm<sup>-1</sup> proved the presence of Al<sub>2</sub>O<sub>3</sub> film. However, typical absorption bands of triazine ring and allyl groups could not be observed from FT-IR spectra with Na<sub>2</sub>CO<sub>3</sub> and Na<sub>2</sub>SO<sub>3</sub> supporting electrolytes. Besides, there were even no absorption bands of Al<sub>2</sub>O<sub>3</sub> while Na<sub>2</sub>SO<sub>3</sub> (pH=6.32) was used as electrolytes, which owed to the acidity reacting with Al<sub>2</sub>O<sub>3</sub> and Al. In addition, the change of pH values before and after polymerization in Na<sub>2</sub>CO<sub>3</sub> (10.25 ~ 10.31), and Na<sub>2</sub>SO<sub>3</sub> (6.32 ~ 7.61) electrolyte was slight, while pH of NaNO<sub>2</sub> electrolyte solution varied from 7.17 to 9.28.

The above results indicated that NaNO<sub>2</sub> was the ideal supporting electrolyte for electrochemical polymerization of DAN on aluminum surface.

### 3.2. Electrochemical polymerization of DAN by cyclic voltammetry and mechanism analysis

The conventional cyclic voltammetry (CV) is regarded as a large potential amplitude technique. Additionally, it is still a very convenient tool that provides a general view of electro-chemical reaction process. Qualitative differences in the shape of CV curves may provide useful information on the impact of the changes on electrochemical response [23]. Therefore, cyclic voltammetry was carried out to understand the polymerization mechanism of DAN in NaNO<sub>2</sub> solution. The aluminum electrode was polarized in 0.15 M aqueous NaNO<sub>2</sub> solution with/without DAN monomer between open circuit potential (E<sub>ocp</sub>) and 1.70 V in positive direction then back to -0.70V in negative direction.
Figure 2. Cyclic voltammetry on aluminum surface in 0.15M NaNO₂ aqueous solution without DAN monomer, T=298 K, | dE/dt | =10 mVs⁻¹

The two cycles of reference were recorded during the polarized of aluminum in 0.15 M NaNO₂ aqueous solution without DAN monomer (Fig. 2). The open circuit potential (Eₒcp) was -0.23 V. With the scanning potential changing from -0.23 to 1.70 V, the weaker current was firstly observed at -0.23 V and gradually become bigger to a high current peak at E₁ (0.32 V), related to the oxidation of aluminum, which covered throughout the entire potential range and formed a broad peak remarked as peak I. In NaNO₂ solution, the aluminum plate was positively polarized by the reactions of electrochemical dissolution. The process was considered as follows (Eqs. (1) - (3)) [24]:

\[
\text{Al}(ss) + \text{OH}^- \rightarrow \text{Al(OH)}_{\text{ads}} + e^- \quad (1)
\]
\[
\text{Al(OH)}_{\text{ads}} + 2\text{OH}^- \rightarrow \text{Al(OH)}_3_{\text{ads}} + 2e^- \quad (2)
\]
\[
\text{Al(OH)}_3_{\text{ads}} + \text{OH}^- \rightarrow \text{Al(OH)}_4^- + ss \quad (3)
\]

where ‘ss’ in the equations represented the bare surface site of aluminum.

Then, a sharp rise of current was observed at E₂ (1.11V) and remarked as peak II, due to the oxidation of the OH⁻ and NO₂⁻. The reaction equations were showed as follows [25]:

\[
\text{NO}_2^- \rightarrow \text{NO}_2 + e^- \quad (4)
\]
\[
\text{H}_2\text{O} + \text{NO}_2^- \rightarrow \text{NO}_3^- + 2\text{H}^+ + 2e^- \quad (5)
\]
\[
2\text{NO}_2^- \rightarrow \text{NO}_3^- + \text{NO} + e^- \quad (6)
\]
\[
2\text{NO}_2^- \rightarrow 2\text{NO}_2\cdot + 2e^- \quad \text{N}_2\text{O}_4 \quad (7)
\]
\[
4\text{OH}^- \rightarrow 2\text{H}_2\text{O} + \text{O}_2\uparrow + 4e^- \quad (8)
\]
In this process, there could be several possible reactions. $\text{NO}_2^-$ could be oxidized directly with generating $\text{NO}_2$ or $\text{NO}_3^-$. $\text{NO}_3^-$ and $\text{NO}$ could also be generated from disproportionation reaction of two equivalents $\text{NO}_2^-$ (Eq (6)). Nitrogen dioxide intermediate ($\text{NO}_2^\bullet$) produced by oxidation of $\text{NO}_2^-$ could dimerize to produce $\text{N}_2\text{O}_4$ (Eq (7)) [26]. The $\text{NaNO}_2$ electrolyte could hydrolyze in water with OH$^-$ being generated. Therefore, reaction (8) occurred due to the supply of OH$^-$. Lots of bubbles could be observed on aluminum surface and irritant gas could be smelt simultaneously. No reduction peak appeared when scanning was carried out in negative direction because of $\text{Al}_2\text{O}_3$ oxide film on the aluminum surface. In the second cycle, the current density decreased dramatically due to the passivating nature of the aluminum oxide layer formed in the first cycle.

\[ \text{NaNO}_2 + \text{H}_2\text{O} \rightarrow \text{NaOH} + \text{NO}_2 \]

\[ \text{NO}_2^\bullet + \text{NO}_2 \rightarrow \text{N}_2\text{O}_4 \]

\[ \text{OH}^- + \text{H}_2\text{O} \rightarrow \text{H}_2\text{O} + \text{H}_2\text{O} \]

**Figure 3.** Cyclic voltammetry on the aluminum in 0.15 M NaNO$_2$ aqueous solution with 5 mM DAN monomer, $T=298$ K, $|\text{d}E/\text{d}t|=10$ mV$s^{-1}$

Two anodic peaks were also observed when the aluminum plate was polarized in the aqueous NaNO$_2$ solution with DAN monomer at a lower open circuit potential ($E_{ocp}'$) -0.57 V, which was different to $E_{ocp}$ (Fig. 3). The peak $\square'$ at -0.57 V was similar to the feature in the case of blank NaNO$_2$ solution, but $E_1$ (0.32 V) shifted to higher potential $E_1'$ (0.40 V). It was considered that the reaction between aluminum ions and DAN produces thin monomer layer on the aluminum plate, depressing the oxidation of aluminum. Also, the maximum current density responding to $E_1'$ increased from $I_1$ (0.49 mAcm$^{-2}$) to $I_1'$ (0.61 mAcm$^{-2}$) (Fig. 4). It was supposed that the thin monomer layer was formed by the reaction between Al and DAN generating Al-DAN complexes slight white film after scanning from $E_{ocp}'$ to 1.70 V. The current density of peak $\square'$ sharply decreased than that of the blank solution ($i_x'<i_x$, Fig. 4) and no bubbles could be seen on aluminum surface and no irritant gas could be smelt. It is suggested that the oxidation and polymerization of DAN took place [11], and the formation of PDA film inhibited direct electrolysis of OH$^-$ and NO$_2^-$. No reduction peak appeared when scanning was carried out from 1.70 to -0.70 V in negative direction. The absence of any reduction peak indicated that the depolymerization of polymeric nanofilm on aluminum surface did not take place, since the PDA film was also insulated like Al$_2$O$_3$ film [10]. In the second cycle, the current density decreased...
more significantly than that of the blank due to the formation of PDA film and aluminum oxide layer formed in the first cycle, which proved to be an excellent barrier to inhibit electron transfer. The white film was observed on aluminum surface after the 1st scan, which revealed the obvious formation of PDA film.

Figure 4. Comparision of the first cycle with/without DAN in 0.15 M NaNO$_2$ aqueous solution

In order to better understand the process of electrochemical polymerization of DAN on aluminum surface, the upper potential (2.10V) of CV was carried out (Fig. 5) and X-ray photoelectron spectroscopy (XPS) was also used to analyze the PDA film.

A new strong peak $\square'''$ started to appear at 1.75 V with the upper limit of scan increasing, which did not appear under 1.70 V scan potential (Fig. 3). It is attributed to the electrolysis of OH$^-$ and NO$_2^-$, since lots of bubbles could be seen on aluminum surface and irritant gas could also be smelt at the same time. It was considered that Al$_2$O$_3$ film and PDA film inhibited electron transfer, namely, depressed the electrolysis of OH$^-$ and NO$_2^-$. Peak $\square'''$ and peak $\square'''$ revealed the formation of the Al-DAN complexes and the PDA film, respectively. The obtained film was consisted of Al$_2$O$_3$ and PDA film. In the above anodization process, the polymerization potential played an important role in creating uniform and packed film, and the potential should be less than 1.75V.

XPS spectra were investigated to confirm the chemical structures of polymeric film on aluminum surface. XPS spectra of samples covered with PDA film were compared to the blank aluminum. The XPS peaks corresponding to oxygen (O1s), nitrogen (N1s), carbon (C1s), sulphur (S2p, S2s) and aluminum (Al2p, Al2s) were analysed (Fig. 6). Only the peaks of C1s (285.0 eV), O1s (532.0 eV), Al2p (73.6 eV) and Al2s (119.7 eV) could be observed for the untreated aluminum plate, while the peaks of N1s (400.7 eV), S2s (228.2 eV), S2p (163.6 eV) originated from the PDA film could be detected. The results also confirmed the formation of PDA film on aluminum surface. The atomic intensity for the relevant elements was different in the graphical representation. In the case of DAN treatment, there were increased amount of N (N1s), C (C1s) and S (S2s, S2p) and decreased amount of O (O1s) and Al (Al2p, Al2s) on the aluminum surface.
Figure 5. Cyclic voltammetry for the aluminum in 0.15 M NaNO₂ aqueous solution with 5 mM DAN monomer at a higher potential, T=298 K, |dE/dt| =10 mVs⁻¹

Figure 6. XPS wide scan spectra of the blank and PDA-covered surfaces in 45° tilt degree. (X-ray anode: Al monochromated 2 nm filament; Aperture: 800 × 2,000 µm)

Based on the above experimental facts and previous studies [28, 29], the reaction mechanism is speculated as follows. The process involved electrochemical oxidation to generate N₂O₄ species, followed by a chemical reaction to produce NO₂⁻. The free radicals (allyl radicals, NO₂⁻, thiol radicals) generated by the electrochemical oxidation experienced chain growth polymerization of DAN, then insoluble polymeric nanofilm was formed. Meanwhile, thiol group and dithiolate anion reacted with aluminum, which was similar to the reaction between triazinedithiols and copper/copper alloy [30]. The allyl radicals reacted with each other or with other free radicals. Fig.7 showed the ideal structure of PDA film and newly formed chemical bonds. The dashed lines represented possible bonding sites marked with different color (pink, green and blue).
Figure 7. Ideal structure of PDA film and possible bonding sites (dashed lines)

Monomer molecules are arranged on the substrate in double electric layer immediately following current application. Thiolate anions become instantly situated in the double electric layer by polarization to form a two-dimensional plane. Polarization decreases with the distance to electrode surface. It becomes difficult for thiolate anions to enter the double electric layer of polymer adhering to the electrode after 6 min polarization at current density of 0.2 mA cm$^{-2}$. The arrangement extent of thiolate anions parallel to each other in lines and perpendicular to the aluminum surface is decreasing with the polymer growth. This arrangement is due to the diffusion of the thiolate anions and electrode polarization. As a result, the outer layer of polymeric nanofilm is composed of allyl group. Thus, the surface properties of DAN-treated aluminum could be potentially used for adhesion in future.

3.3. Electrochemical polymerization of DAN by galvanostatic method

The thickness and weight of PDA film on aluminum plate increase with electrochemical polymerization time prolonging, as shown in Table 1. When the electrochemical polymerization time is over 6 min, the thickness and weight vary slightly. It can be speculated that the PDA film obtained by 6 min electrochemical polymerization is more compact and insulated, which could depress the further formation of PDA film and the depolymerization reaction could happen.

The morphology of polymeric nanofilm on aluminum surface prepared by galvanostatic method was observed by SEM. It can be seen that the electrochemical polymerized aluminum surfaces (b, c, d, e) are covered by PDA film compared to Al reference (a). The fringes of aluminum surface become to disappear due to the formation of polymeric nanofilm from (a) to (e). Also, the coverage of polymeric nanofilm on aluminum surface becomes higher. All of the results demonstrate the continuous formation of polymeric nanofilm on aluminum surface with the polymerization time increasing. When the electrochemical polymerization time reaches 6 min, the most homogenous and compact film is obtained.

4. CONCLUSIONS

NaNO₂ proved to be the ideal supporting electrolyte for electrochemical polymerization of DAN on aluminum surface. The PDA film was successfully prepared on aluminum plate by cyclic voltammetry and galvanostatic method. The obtained film was consisted of Al₂O₃ and PDA. The free radicals, which were produced by the electrochemical oxidation experienced reaction of radical polymerization and the insoluble polymeric nanofilm was obtained. Also, the optimal electrochemical polymerization time of DAN at current density of 0.2 mA/cm² in the NaNO₂ solution is 6 min. The outer surface of nanofilm was composed of allyl groups, which had the affinity to rubbers. This technique was an environment-friendly method for promoting both adhesion and anti-corrosion of aluminum material.
